A simple microstructure return model explaining microstructure noise and Epps effects

Abstract

We present a simple microstructure model of financial returns that combines (i) the well-known ARFIMA process applied to tick-by-tick returns, (ii) the bid-ask bounce effect, (iii) the fat tail structure of the distribution of returns and (iv) the non-Poissonian statistics of inter-trade intervals. This model allows us to explain both qualitatively and quantitatively important stylized facts observed in the statistics of microstructure returns, including the short-ranged correlation of returns, the long-ranged correlations of absolute returns, the microstructure noise and Epps effects. According to the microstructure noise effect, volatility is a decreasing function of the time scale used to estimate it. Paradoxically, the Epps effect states that cross correlations between asset returns are increasing functions of the time scale at which the returns are estimated. The microstructure noise is explained as the result of the negative return correlations inherent in the definition of the bid-ask bounce component (ii). In the presence of a genuine correlation between the returns of two assets, the Epps effect is due to an average statistical overlap of the momentum of the returns of the two assets defined over a finite time scale in the presence of the long memory process (i).

1 Introduction

In the last decade, a lot of attention has been directed towards gathering empirical facts and developing theoretical understanding of the microstructure (i.e., on tick-by-tick scales) characterizing the behavior of stocks prices, their corresponding returns and volatility (see for instance [1, 4, 5, 7, 9, 16, 22, 23]). These investigations have revealed seemingly contradictory stylized facts in the statistical behavior of the dynamics of prices and returns. Let us mention the well-known short-ranged correlations of returns together with the long-ranged correlations of the absolute value of returns [8, 10], the microstructure noise effect of realized volatility [1, 7, 23] and the Epps effect of cross-correlations of returns [7, 11]. The microstructure noise effect refers to the observation that volatility is a decreasing function of the time scale used to estimate it. In contrast, the Epps effect describes the fact that cross correlations between asset returns are increasing functions of the time scale at which the returns are estimated. These stylized facts are observed in a large variety of financial markets, including stocks, futures and options and they are thus considered as universal properties that are inherent to high-frequency financial markets data. However, there is still no theoretical model that can account simultaneously for the four mentioned stylized facts (see however Ref.[12] which emphasizes that the asynchrony of trades as well as the decimalization of stock prices are large contributors to the Epps effect. This paper also contains a review of previous papers attempting to explain the Epps effect). It is the purpose of the present paper to fill this gap and propose simple model for the microstructure of returns that describes these stylized facts both at a qualitative and quantitative level.

Our model of tick-by-tick returns contains the following ingredients: (i) a long-memory centered Gaussian variable following an ARFIMA process; (ii) a sign bounce generalizing the bid-ask bounce effect governed by a quasi-periodic Bernouilli random variable; (iii) a random amplitude drawn from a fat-tail distribution; and (iv) the specification of the iid sequence of inter-trade intervals distributed according to a given probability density function chosen as a simple Weibull or a generalized gamma distribution. We show that the microstructure noise effect results simply from the negative return correlations inherent in the definition of the sign bounce component (ii). In the presence of a genuine correlation between the returns of two assets, the Epps effect appears due to an average statistical overlap of the momentum of the returns of the two assets defined over a finite time scale in the presence of the long memory process (i). In our microstructure framework, correlations between two assets correspond to buy or sell pressure exerted on both of them, but not exactly at the same time (except if the correlation is 1), due to possible delays in implementation as well as herding effects between trading decisions resulting from human decisions or algorithmic high-frequency trading. We stress that, notwithstanding this long memory (i), the sign bounce process (ii) ensures that auto-correlations of returns are short-lived, in agreement with empirical evidence.

The presentation is organized as follows. Section 2 describes in details our model and derives the quantitative characteristics of the long ranged correlations of the absolute tick-by-tick returns. Section 3 discusses returns correlations in calendar time scale. Significant attention is given to the statistical description of inter-trade time intervals. Section 4 describes quantitatively the statistical properties of the microstructure noise effect in the frame of the proposed model. Then, Section 5 reveals the roots of the Epps effect, as suggested from our microstructure model. Two appendices provide detailed information on the derivation of the analytic expressions used in the main text.

2 Model for the microstructure of financial returns at the tick scale

2.1 Instantaneous returns vs tick-by-tick returns

Let $L(t)$ be the log-price of some asset. The corresponding return $R_\Delta(t)$ as time scale Δ is defined as the increment of the log-price over the time interval $(t-\Delta, t)$

$$R_\Delta(t) = L(t) - L(t-\Delta) \ . \tag{1}$$

In the present work, we develop a phenomenological theory of returns $R_\Delta(t)$ based on the *instantaneous return* $R(t)$ defined as the derivative of log-price $L(t)$:

$$R(t) = \frac{dL(t)}{dt} \ . \tag{2}$$

Knowing the instantaneous returns, the Δ-scale returns $R_\Delta(t)$ are obtained in integral form

$$R_\Delta(t) = \int_{t-\Delta}^{t} R(t')dt' \ . \tag{3}$$

We consider the situation where the instantaneous returns are delta-pulses of the form

$$R(t) = \sum_k r_k \delta(t-t_k) \ . \tag{4}$$

Expression (4) reflects the discrete nature of the process generating changes of log-prices, which occur by jumps $\{r_k\}$ at the ordered tick-by-tick instants $\{t_k\}$:

$$\cdots < t_{k-1} < t_k < t_{k+1} \ldots \qquad (t_0 < 0,\ t_1 > 0)\ . \tag{5}$$

We suggest below that the sequences $\{t_k\}$ and $\{r_k\}$ are mutually statistically independent. Moreover, we assume that the sequences $\{t_k\}$ and $\{r_k\}$ are stationary in the sense that the statistical properties of inter-trade intervals

$$\tau_{k,m} = t_{k+m} - t_k \tag{6}$$

and of pairs (r_{k+m}, r_k) depend only on m.

The instantaneous return $R(t)$ and Δ-scale returns $R_\Delta(t)$ are defined in the *calendar time scale*, where the time is measured in units of seconds, hours, years, and so on. In particular, expressions (3) and (4) are representations of returns and of instantaneous returns in the calendar time scale. Sometimes, it may be more convenient to use the *tick-by-tick time scale*, where one measures time in subsequent trade numbers. In this sense, the sequence $\{r_k\}$ is the representation of instantaneous returns in the tick-by-tick time scale. Hereinafter, we shall discuss in details the interrelation between the instantaneous return $R(t)$ given by (4) defined in calendar time and the returns $\{r_k\}$ in tick-by-tick time.

2.2 Formulation of the model of tick-by-tick returns

Let us now define a simple stochastic model of tick-by-tick returns $\{r_k\}$ of the form

$$r_k := X_k M_k / H_k\ , \tag{7}$$

which captures both the short-range correlation of returns and the long-range correlation of the absolute value of returns. The sequence $\{X_k\}$ is generated by a standard ARFIMA process [13, 14] satisfying the discrete fractional difference equation

$$(1-T)^d X_k = \Upsilon \cdot u_k, \qquad d \in (0, 1/2)\ , \tag{8}$$

where T is the unit tick-lag operator, the u_k's are iid random variables with zero mean and unit variance, Υ is a normalizing constant such that $\rho_0 = 1$ where ρ_m is the correlation function of the ARFIMA process

$$\rho_m := \mathrm{E}\left[X_k X_{k+m}\right]\ . \tag{9}$$

Bearing in mind the bid-ask bounce effect (see for instance [2, 18]), the factor M_k in expression (7) is equal to

$$M_k := (-1)^{\xi_k}\ , \tag{10}$$

where

$$\xi_k := \sum_{s=1}^{k} \iota_s \ . \tag{11}$$

The sequence $\{\iota_s\}$ takes into account the buy–sell structure of subsequent trades (ticks) in the following sense: if the $(s-1)$-th and s-th trades are the same (i.e. both are selling or buying), then $\iota_s = 0$; in the opposite cases, $\iota_s = 1$. We assume in our model that the sequence $\{\iota_s\}$ consists of iid random Bernoulli integers, equal to one with probability p and zero with the complementary probability $q = 1 - p$. The probability q can be interpreted as the measure of distortion with respect to the periodic reference buy-sell process. Indeed, the closer q is to zero, the more likely a buy (sell) trade will be followed by a sell (buy) order. At $q = 0$, the sequences $\{M_k\}$ and $\{r_k\}$ have their signs being exact periodic functions of k, reflecting a perfect periodic buy-sell process that mimics a perfect bid-ask bounce.

Definition 1 *For short, we refer to the parameter q as the* bounce distortion *probability.*

The positive iid denominators $\{H_k\}$ in expression (7) are chosen in such a way that the tick-by-tick returns $\{r_k\}$ possess a fat tail distribution similar to that found in empirical data, as specified in Appendix A.3.

Our model assumes that the sequences $\{X_k\}$, $\{M_k\}$ and $\{H_k\}$ are mutually statistically independent. This implies in particular that the mean values of the tick-by-tick returns $\{r_k\}$ are all equal to zero. It is easy to generalize the theory developed below in the case where the means of $\{r_k\}$ are non-zero.

2.3 Key properties

In Appendix A.1, we show that the correlations $\{\rho_m\}$ defined by (9) of the ARFIMA process $\{X_k\}$ are described with excellent accuracy by the power law

$$\rho_m := \mathrm{E}\left[X_k X_{k+m}\right] \simeq \begin{cases} 1, & m = 0 \\ \digamma(\alpha)\ m^{-\alpha}, & m \geqslant 1, \end{cases} \qquad \digamma(\alpha) := \frac{\Gamma(\frac{1+\alpha}{2})}{\Gamma(\frac{1-\alpha}{2})}, \tag{12}$$

where $\alpha = 1 - 2d \in (0, 1)$.

Appendix A.2 derives that the correlation coefficients of the bounce factors $\{M_k\}$ are given by

$$C_m := \mathrm{E}\left[M_k \; M_{k+m}\right] = e^{-\tilde{q}\; m} \times \begin{cases} (-1)^m, & 0 < q < 1/2, \\ 1, & 1/2 < q < 1, \end{cases}$$
$$\tilde{q} := \ln\left(\frac{1}{|2q-1|}\right) . \qquad (13)$$

The critical value $q_c = 1/2$ divides the interval $q \in (0, 1)$ into two parts, in which the behavior of the correlation coefficients C_m (13) are qualitatively different.

1. For $q \in (0, 1/2)$, C_m is a sign-alternating function of m.
2. For $q \in (1/2, 1)$, C_m is a positive non-oscillating function of its argument m.

The existence of a sign-alternating behavior of C_m for small q's can be expected from our previous remark that the closer q is to zero, the more likely a buy (sell) trade will be followed by a sell (buy) order. Note also that, the closer q is to the critical value $q_c = 1/2$, the more short-ranged becomes C_m. Below, we discuss only the case $q \in (0, 1/2)$, which is consistent with the known stylized fact that subsequent tick-by-tick returns r_k and r_{k+1} are negatively correlated (see for instance [2, 7, 8]).

Appendix A.3 describes the statistical properties that the iid sequence $\{H_k\}$ need to obey in order for the distribution $\phi(r)$ of tick-by-tick returns $\{r_k\}$ to be fat tailed. In the following, we suppose for definiteness that $\phi(r)$ is a Student distribution of the form

$$\phi(r) = \frac{\Gamma\left(\frac{\mu+1}{2}\right)}{b\sqrt{\pi}\,\Gamma\left(\frac{\mu}{2}\right)} \left(1 + \frac{r^2}{b^2}\right)^{-\left(\frac{\mu+1}{2}\right)} , \qquad (14)$$

where corresponds to a tail exponent μ.

2.4 Correlation of tick-by-tick returns

Putting all the properties described in the previous subsection together, the correlation function of the tick-by-tick returns $\{r_k\}$ defined by (7)

$$\mathcal{K}_m := \mathrm{E}\left[r_k r_{k+m}\right] = \mathrm{E}\left[X_k X_{k+m} M_k M_{k+m} / H_k H_{k+m}\right] , \qquad (15)$$

can be obtained explicitly. Taking into account the mutual statistical independence of the factors $\{X_k\}$, $\{M_k\}$ and of the iid denominators $\{H_k\}$, and using relations, (12), (13), one has

$$\mathcal{K}_m = \varepsilon_2 \, \mathcal{B}_m \ ,$$

$$\mathcal{B}_m := e^{-\tilde{q}\ m} \begin{cases} 1, & m = 0 \ , \\ \gamma \, (-1)^m m^{-\alpha}, & m \geqslant 1, \end{cases} \qquad \gamma := \Gamma(\alpha) \frac{\varepsilon_1^2}{\varepsilon_2} \ , \tag{16}$$

where $\varepsilon_\theta := \mathrm{E}\left[H_k^{-\theta}\right]$ is the inverse moment of the denominators $\{H_k\}$ given by expression (A.18).

Figure 1 shows the autocorrelation function $\mathcal{K}_m/\varepsilon_2$ for $\alpha = 0.1$ and for different values of the bounce distortion probability q.

2.5 Long-range correlations of absolute returns

Consider now the autocorrelation function

$$\mathcal{A}_m(\theta) := \frac{\mathrm{E}\left[|r_k|^\theta \, |r_{k+m}|^\theta\right] - \mathrm{E}^2\left[|r_k|^\theta\right]}{\mathrm{E}\left[|r_k|^{2\theta}\right] - \mathrm{E}^2\left[|r_k|^\theta\right]} \tag{17}$$

of power θ of the absolute values of the tick-by-tick returns.

Using the quadratic approximation (A.26) and relations (A.18), (A.20), we can rewrite expression (A.21) in the form

$$\mathcal{A}_m(\theta) \simeq \begin{cases} 1, & m = 0, \\ \\ \chi \, m^{-\sigma}, & m \geqslant 1, \end{cases} \qquad \sigma := 2\alpha \in (0, 2), \tag{18}$$

where the factor χ is given by relation (A.28). It follows from the analysis of Appendix A.4 that the power law in (18) constitutes an extremely accurate description of $\mathcal{A}_m(\theta)$ for a wide range of the parameters μ, θ and for any $\sigma \in (0, 2)$. This is visualized in the log-log representation of figure 2, which shows the exact dependence of the autocorrelation function of the absolute returns.

The main properties the correlation function (18) of the absolute returns are as follows.

1. Relation (18) means that the correlations of the absolute returns are long-ranged if the exponent σ is sufficiently small (less than 1 in order to technically qualify as “long memory” [6]). Empirically, typical values of the exponent are found in the range $\sigma \in (0.2, 0.4)$ [8].

2. The exponent σ is an empirically observable parameter as it can be easily obtained from an appropriate statistical analysis of financial data.

This is in contrast with the exponent α of the correlation of returns given by (16), which is unobservable due to the distortion of the bid-ask bounce that remove the information on this underlying power decay.

3. As shown in Appendix A.4, the power law decay of the correlation of the absolute returns has the same tail exponent σ for any $\theta \in (0.5, 1.5)$, for which the quadratic approximation (A.26) of the function $\widetilde{\mathcal{F}}(\theta, \rho)$ (A.22) is highly accurate.

4. The shape of the correlation function $\mathcal{A}_m(\theta)$ as a function of θ does not depend on m and σ but is different for different values of the exponent μ. The dependences on θ of the normalized autocorrelation function

$$\Lambda(\theta) := \frac{\mathcal{A}_m(\theta)}{\max_\theta \mathcal{A}_m(\theta)}, \qquad m > 0 \ , \tag{19}$$

for different values of the exponent μ of the Student distribution $\phi(r)$ (14), are shown in figure 3. We observe a shape similar to the daily returns correlations shown in Ref. [10].

3 Correlation of returns in calendar time scale

In the previous sections, we have described the statistical properties of returns of our model in the tick-by-tick time scale. Henceforth, we present a study of the statistical properties of instantaneous returns $R(t)$ (4) and of Δ-scale returns $R_\Delta(t)$ (3) in calendar time scale. This allows us to describe the microstructure noise and Epps effects.

3.1 Correlation function of instantaneous returns

The covariation function of instantaneous returns $R(t)$ (4) in the calendar time scale representation defined by $K(\tau) := \mathrm{E}\left[R(t)R(t+\tau)\right]$ is obtained from the autocorrelation function $\mathcal{B}_m$ (16) at the tick-by-tick time scale by relation

$$K(\tau) = \nu\, \varepsilon_2 \left[\delta(\tau) + B(\tau)\right] \ , \tag{20}$$

where

$$B(\tau) = \sum_{m=1}^{\infty} \mathcal{B}_m f_m(|\tau|) \ , \tag{21}$$

ε_2 is the variance of the tick-by-tick returns, ν is the mean rate of returns given by

$$\nu = 1/\bar{\tau}, \qquad \bar{\tau} := \mathrm{E}\left[\tau_{k,1}\right] \ , \tag{22}$$

while $f_m(\tau)$ ($\tau > 0$) is the probability density function of tick-by-tick time interval durations $\tau_{k,m}$ (6). A short outline of the derivation of relation (21) is given in Appendix B.1. It is convenient to use the mean time duration $\bar{\tau}$ between subsequent trades as the unit time to scale all calendar times.

Definition 2 *In the following, we scale all time scales by the intertrade mean duration $\bar{\tau}$, referring to this transformation as the "calendar time scale representation".*

In the calendar time scale representation, we have $\bar{\tau} \equiv 1$ and relation (20) takes the reduced form

$$K(\tau) = \varepsilon_2 \left[\delta(\tau) + B(\tau)\right]. \qquad (23)$$

3.2 Spectrum of instantaneous returns

In what follows, we need to evaluate the spectrum of function $K(\tau)$ (23)

$$\tilde{K}(\omega) := \frac{\varepsilon_2}{\pi} \int_0^\infty K(\tau) \cos(\omega\tau) d\tau \ . \qquad (24)$$

Using (21), (23), we obtain

$$\tilde{K}(\omega) = \frac{\varepsilon_2}{2\pi} \left[1 + \tilde{B}(\omega)\right], \qquad (25)$$

where

$$\tilde{B}(\omega) := 2 \int_0^\infty B(\tau) \cos(\omega\tau) d\tau = 2\mathrm{Re}\left[\sum_{m=1}^{\infty} \mathcal{K}_m \hat{f}_m(i\omega)\right] \qquad (26)$$

and $\hat{f}_m(s)$ is the Laplace image of the probability density function $f_m(\tau)$

$$\hat{f}_m(s) := \int_0^\infty f_m(\tau) e^{-s\tau} d\tau. \qquad (27)$$

Although some authors are found evidence of long-ranged correlations between different inter-trade time intervals [15], we, along with Ref. [20], suggest henceforth that tick-by-tick instants $\{t_k\}$ are such that the random inter-trade durations $\{\tau_k\}$ are iid random variables with the same probability density function $f(\tau)$.

Assertion 1 *Our microstructure return model* (7) *of tick-by-tick returns is fully defined when supplemented by the specification of the iid sequence $\{\tau_k\}$ of inter-trade intervals distributed according to the probability density function $f(\tau)$.*

Within our microstructure return model, the probability density functions $f_m(\tau)$ are equal to m-tiple convolutions of $f(\tau)$. Accordingly, relation (26) takes the form

$$\tilde{B}(\omega) := 2\mathrm{Re}\left[\sum_{m=1}^{\infty} \mathcal{K}_m \hat{f}^m(i\omega)\right]. \tag{28}$$

Substituting the expression (16) for the autocorrelation function of the tick-by-tick returns and after summing the series, we obtain

$$\tilde{B}(\omega) = -\frac{2(1-2q)\gamma}{\Gamma(1+\alpha)} \int_0^\infty \mathrm{Re}\left[\frac{\hat{f}(i\omega)}{e^{u^{1/\alpha}} + (1-2q)\hat{f}(i\omega)}\right] du. \tag{29}$$

The factor γ is defined from (16) with (12).

3.3 Statistics of inter-trade time intervals

In what follows, we use relation (29) to analyze quantitatively the microstructure noise and Epps effects. The characteristics of these effects depend essentially on the statistics of the inter-trade time intervals. Under the condition that the inter-trade durations are iid, all information about their statistics is contained in the probability density function $f(\tau)$. We thus first discuss possible models for this probability density function.

In the econometric literature, the statistics of inter-trade intervals has been studied empirically and parametric models have been proposed (see, for instance, [15, 17, 19]). Here, we discuss a few analytical models for the probability density functions $f(\tau)$, which provide reasonable fits to the empirical distributions of inter-trade intervals while at same time possess a convenient analytical expression for their Laplace images $\hat{f}(s)$. Having such analytical approximations is very useful for the determination of the spectrum $\tilde{B}(\omega)$ (29), which is defined in terms of the Laplace image $\hat{f}(i\omega)$ of the probability density function of inter-trade intervals expressed in terms of the imaginary argument $i\omega$.

A model often used to represent the distribution of inter-trade intervals is the Weibull distribution

$$f(\tau) = \lambda w(\lambda\tau;\beta), \qquad w(\tau;\beta) := \beta\tau^{\beta-1}e^{-\tau^\beta}, \tag{30}$$

where β is the shape parameter and λ is the scaling parameter. The corresponding survival probability $Q(\tau) := \int_\tau^\infty f(u)du$ is given by expression

$$Q(\tau) = W(\lambda\tau;\beta), \qquad W(\tau;\beta) := \int_\tau^\infty w(u;\beta)\,du = e^{-\tau^\beta}. \tag{31}$$

In the reduced time scale representation in which the unit duration is taken as the mean inter-trade interval $\bar{\tau}$, the Weibull distribution depends only on the shape parameter β, while the scale parameter λ is defined by the condition

$$\bar{\tau} = \int_0^\infty Q(\tau) d\tau \equiv 1 \qquad \Rightarrow \qquad \lambda = \lambda_w(\beta) := \Gamma\left(\frac{1+\beta}{\beta}\right) . \tag{32}$$

Figure 4 presents typical time sequences $\{t_k\}$ of trades with $t_k = \sum_{i=1}^k \tau_i$, where the inter-trade intervals τ_i's are drawn from the Weibull distribution with shape parameters $\beta = 0.5; 1; 2$ respectively. Notwithstanding the mutual independence of the inter-trade intervals $\{\tau_k\}$, one can observe clustering for $\beta < 1$ and quasi-periodicity for $\beta > 1$.

However, the Weibull distribution family has some shortcoming. First, its Laplace image does not have a simple analytical representation for any value of β. Second, it has not enough shape parameters in order to fit the empirical probability density function over the whole range of τ values for which the empirical probability density function is still measured accurately. Indeed, using $\beta \simeq 0.75 \div 0.85$, the Weibull distribution provides a rather accurate representation of the empirical distribution at small and intermediate values of τ. But it goes to zero too fast for large τ values, compared with the slow decay of the empirical probability density function [17]. This justifies using some more flexible distributions, which are related to the Weibull family. One such possibility is the generalized gamma distribution (GGD)

$$f(\tau) = \lambda g(\lambda\tau; \vartheta, \beta), \qquad g(\tau; \vartheta, \beta) := \frac{\beta \tau^{\vartheta - 1}}{\Gamma(\vartheta/\beta)} \, e^{-\tau^\beta} \ . \tag{33}$$

Its survival probability is

$$Q(\tau) = G(\lambda\tau; \vartheta, \beta), \qquad G(\tau; \vartheta, \beta) := \frac{\Gamma\left(\vartheta/\beta, \tau^\beta\right)}{\Gamma\left(\vartheta/\beta\right)} \ , \tag{34}$$

where $\Gamma(a, z)$ is the incomplete gamma function. The scale parameter λ is given by

$$\lambda = \lambda_g(\vartheta, \beta) := \frac{\Gamma[(1+\vartheta)/\beta]}{\Gamma(\vartheta/\beta)} \tag{35}$$

so as to ensure that the mean time duration between trades is unity.

From the point of view of the feasibility of analytical calculations of the integral (29), the GGD has the nice property of having analytical expressions for its Laplace images for any rational β and for arbitrary shape parameter ϑ. Analytical expressions of the Laplace images of the GGD (33), for some rational values of it shape parameter β, are given in Appendix B.2.

Figure 5 shows the survival functions of the Weibull distribution (31) for $\beta = 0.8$ and of the generalized gamma distribution (34), for the same $\vartheta = 0.8$ and for $\beta = 2/3$, $1/2$ and $\beta = 1/3$. Figure 6 compares the function $\tilde{B}(\omega)$ (29) obtained for a Poissonian statistics of the tick-by-tick times $\{t_k\}$, where

$$f(\tau) = e^{-\tau} \qquad \Leftrightarrow \qquad \hat{f}(s) = \frac{1}{1+s} \ , \tag{36}$$

to the two functions $\tilde{B}(\omega)$ for the GGDs for $\theta = 0.8$ and $\beta = 1/2; 2/3$, for which the Laplace images of the probability density function are given by the analytical expressions (B.9), (B.10) and (B.13), (B.14).

All curves represented in figure 6 coincide at $\omega = 0$, which is the consequence of the fact that $\tilde{B}(0)$ does not depend on the shape of the distribution $f(\tau)$ of the inter-trade interval durations. Note however the significant differences between the three realizations of $\tilde{B}(\omega)$ at $\omega \neq 0$, which emphasizes the difference between the exponential probability density function (36) and the GGD.

3.4 Short-ranged correlations of discrete returns in calendar time

In section 2, we have demonstrated that our microstructure return model predicts that the range of the correlations of the tick-by-tick returns is controlled essentially by the bounce distortion probability q (see figure 1). In particular, if q is close to zero, then the autocorrelation $\mathcal{K}_m$ (16) of the tick-by-tick returns is a long-ranged (sign-alternating) function of m. In contrast, if q is close to the critical value $q_0 = 1/2$, the correlation of the tick-by-tick returns becomes short ranged (as an illustration, see the upper and lower plots in figure 1). We now show that, even for small q's including $q = 0$, the correlation of the Δ-scale returns $R_\Delta(t)$ (3) in calendar time is short-ranged, as a result of the washing action of the random inter-trade intervals $\{\tau_k\}$.

To demonstrate this result, we rewrite the Δ-scale returns in the more convenient form

$$R_\Delta(t) = \Pi_\Delta(t) \otimes R(t), \qquad \Pi_\Delta(t) := \begin{cases} 1, & t \in (0, \Delta), \\ 0, & t \notin (0, \Delta), \end{cases} \tag{37}$$

where the symbol $\otimes$ represents the convolution operation. Using (23) and (37), the correlation function of the Δ-scale returns $R_\Delta(t)$ is given by the convolution

$$\begin{gathered} K_\Delta(\tau) := \mathrm{E}\left[R_\Delta(t) R_\Delta(t+\theta)\right] = K(\tau) \otimes \mathcal{T}_\Delta(\tau) = \\ \varepsilon_2 \left[\delta(\tau) + B(\tau)\right] \otimes \mathcal{T}_\Delta(\tau) \ , \end{gathered} \tag{38}$$

where

$$\mathcal{T}_\Delta(\tau) := \begin{cases} \Delta - |\tau|, & |\theta| < \Delta, \\ 0, & |\tau| > \Delta. \end{cases} \tag{39}$$

For the numerical estimation of the function $K_\Delta(\tau)$, we use relation (B.17), which is directly derived from relation (38). Figure 7 shows the ratio $K_\Delta(\tau)/K_\Delta(0)$, for $\Delta = 1$ and for different values of the bounce distortion probability q. One can observe the short range nature of the correlations of the Δ-scale returns in calendar time for all q values. Note the fact that the correlations become negative before decaying to zero. The results shown in figure 7 use the GGD (33) for the distribution $f(\tau)$ of the inter-trade intervals, with $\vartheta = 0.8$ and $\beta = 2/3$. Analogous plots for $q = 0$ and for different values of Δ are shown in figure 8.

4 Microstructure noise effect

4.1 Basic notions

The goal of this section is to show that our model provides a natural set-up for the microstructure noise effect [1, 2, 3, 4, 5, 8]. The microstructure noise effect refers to the following phenomenon. Let us consider the realized volatility[1], equal to

$$\hat{D}(\Delta, T) = \frac{1}{T} \sum_{k=1}^{\lfloor T/\Delta \rfloor} R_\Delta^2(k\Delta) \ . \tag{40}$$

If $R_\Delta(t)$ is a stationary and ergodic process, then the realized volatility (40) converges in probability as T goes to infinity to

$$D(\Delta) := \frac{1}{\Delta} \mathrm{E}\left[R_\Delta^2(t)\right] , \tag{41}$$

which is, by definition, the average volatility density over intervals of duration Δ.

The geometric Brownian motion (GBM) $L(t) = D \cdot W(t)$ is the simplest and often used first-order model of price dynamics, where $W(t)$ is the standard Wiener process. The GBM is such that the volatility density $D(\Delta)$ does not depend on Δ ($D(\Delta) \equiv D$), so that its estimation is in principle independent of the time durations Δ. In addition, for GBM processes, the volatility is *observable* as, for $\Delta \to 0$ and for any given observation interval of duration $T = \text{const}$, the realized volatility converges in probability to the volatility density D:

---

[1] In this context, volatility is defined as the variance of the log-price increments over a given time interval of duration Δ.

$$\hat{D}(\Delta, T) \xrightarrow{\text{P}} D, \qquad \Delta \to 0, \qquad T = \text{const} \ . \tag{42}$$

Real financial markets depart from the ideal GBM and exhibit the *microstructure noise effect*, i.e., for small durations Δ that are comparable to the mean time interval $\bar{\tau}$ between subsequent trades, the realized volatility is positively biased. Mathematically, this means that $D(\Delta)$ defined by expression (41) increases as Δ decreases.

Assertion 2 *The next subsection demonstrates that the microstructure noise effect results simply from the negative return correlations inherent in the microstructure model proposed in the present paper.*

4.2 Strength of microstructure noise effect

In order to describe quantitatively the microstructure noise effect, let us calculate the function $D(\Delta)$ defined by expression (41) in the frame of our microstructure returns model. Due to equality (38), one has

$$D(\Delta) = \frac{1}{\Delta} K_\Delta(0) = \varepsilon_2 \left(1 + \frac{2}{\Delta} \int_0^\infty \mathcal{T}_\Delta(\tau) B(\tau) d\tau \right) \ . \tag{43}$$

Definition 3 *We defined respectively by "true" and "microstructure" volatilities the following limit values*

$$D_{\text{true}} := \lim_{\Delta \to \infty} D(\Delta) \ , \qquad D_{\text{micro}} := \lim_{\Delta \to 0} D(\Delta) \ . \tag{44}$$

The ratio

$$\mathcal{S} := \frac{D_{\text{micro}}}{D_{\text{true}}} \tag{45}$$

defines the strength of the microstructure noise effect.

The ratio $\mathcal{S}$ (45) has the following intuitive economic meaning. It is equal to the dimensionless ratio of the realized volatility $D(\Delta)$ (41) at the micro ($\Delta \to 0$) and at the macro ($\Delta \to \infty$) scales. This justifies that $\mathcal{S}$ provides a convenient quantitative characterization of the strength of the microstructure noise effect.

The dependence of the strength $\mathcal{S}$ (45) of the microstructure noise effect with respect to the parameters of our microstructure noise model is obtained as follows. From expressions (43), (29) and (39), we obtain

$$D_{\text{micro}} = \varepsilon_2, \qquad D_{\text{true}} = \varepsilon_2 [1 + \tilde{B}(0)], \tag{46}$$

so that,

$$\mathcal{S} = \frac{1}{1+\tilde{B}(0)}. \tag{47}$$

In view of relation (29), one has

$$\tilde{B}(0) = -\frac{2(1-2q)\gamma}{\Gamma(1+\alpha)} \int_0^\infty \frac{du}{e^{u^{1/\alpha}} + 1 - 2q} \ . \tag{48}$$

Expression (47) with (48) shows that $\mathcal{S}$ does not depend on the shape of the probability density function $f(\tau)$ of the inter-trade interval durations. It does depend on the other parameters α, q, μ of the model, where α is the unobservable exponent of the power law correlation (12) of the auxiliary ARFIMA process $\{X_k\}$, q is the bounce distortion probability, and μ is the exponent of the power law describing the tail of the probability density function $\phi(r)$ (14) of the tick-by-tick returns. While α is not directly observable, it can be derived from the the observable exponent σ of the power law dependence of the correlation (18) of the absolute tick-by-tick returns via the equality $\sigma = 2\alpha$. Figures 9-11 illustrate the dependence of the strength $\mathcal{S}(\alpha, q, \mu)$ of the microstructure noise effect on these three parameters.

A further quantification of the strength of the microstructure noise effect is obtained by introducing the generalization of the strength $\mathcal{S}$ (45) defined by

$$\mathcal{S}_\Delta := \frac{D(\Delta)}{D_{\text{true}}} \ , \tag{49}$$

which now depends on the interval duration Δ over which the returns $R_\Delta(t)$ are defined. Figure 12 illustrates the dependence of $\mathcal{S}_\Delta$ for $\alpha = 0.1$ ($\sigma = 0.2$), $\mu = 5$ and for different values of the bounce distortion probability q.

5 Epps effect

5.1 Epps effect: basic notions

The microstructure return model introduced in the present paper is able to identify the roots of the Epps effect [11, 21], as we now demonstrate.

For this, let us describe the Epps effect by using the notations introduced above. Let us consider the instantaneous returns $R_1(t)$ and $R_2(t)$ of two assets. Analogously to (37), the Δ-scale returns of the two assets during a time interval of duration Δ can be expressed with the relations

$$R_{1,\Delta}(t) = \Pi_\Delta(t) \otimes R_1(t), \qquad R_{2,\Delta}(t) = \Pi_\Delta(t) \otimes R_2(t) \ . \tag{50}$$

The Epps effect is observed on a quantity that is analogous to (41), except that under the expectation sign the square return $R^2_\Delta(t)$ is replaced by the product of the two different returns $R_{1,\Delta}(t)$ and $R_{2,\Delta}(t)$

$$D_{1,2}(\Delta) := \frac{1}{\Delta} \mathrm{E}\left[R_{1,\Delta}(t) R_{2,\Delta}(t)\right] \ . \tag{51}$$

$D_{1,2}(\Delta)$ is thus a measure of inter-dependence between the two assets.

It is convenient to introduce a normalized version of $D_{1,2}(\Delta)$ (51). For this, we consider the simple case where the returns $R_1(t)$ and $R_2(t)$ are statistically equivalent in the sense that $D_1(\Delta) = D_2(\Delta) = D(\Delta)$, where

$$D_1(\Delta) := \frac{1}{\Delta} \mathrm{E}\left[R^2_{1,\Delta}(t)\right] , \qquad D_2(\Delta) := \frac{1}{\Delta} \mathrm{E}\left[R^2_{2,\Delta}(t)\right] \ . \tag{52}$$

The normalized version of $D_{1,2}(\Delta)$ (51) is defined as

$$\mathcal{S}^{1,2}_\Delta := \frac{D_{1,2}(\Delta)}{D_{\text{true}}}, \qquad D_{\text{true}} := \lim_{\Delta \to \infty} D(\Delta). \tag{53}$$

Now we are ready to formulate the Epps effect.

Definition 4 *Consider two assets whose* Δ*-scale returns* $R_{1,\Delta}(t)$ *and* $R_{2,\Delta}(t)$ *at scale* Δ *are correlated so that the following limit is positive*

$$\lim_{\Delta \to \infty} \mathcal{S}^{1,2}_\Delta > 0 \ . \tag{54}$$

The Epps effect corresponds to the fact that $\mathcal{S}^{1,2}_\Delta$ (53) *is a monotonically increasing function of the argument* Δ*, and which vanishes as* $\Delta \to 0$*.*

5.2 Epps effect paradox

Before explaining the Epps effect in the frame of our microstructure returns model, it is illuminating to first discuss a paradox that emerges when comparing the dependence with Δ of the two similar functions

$$D(\Delta) = \frac{1}{\Delta} \mathrm{E}\left[R^2_{1,\Delta}(t)\right] \quad \text{and} \quad D_{1,2}(\Delta) = \frac{1}{\Delta} \mathrm{E}\left[R_{1,\Delta}(t) R_{2,\Delta}(t)\right] \ . \tag{55}$$

According to the microstructure noise effect discussed in the previous section, the first $D(\Delta)$ is a *decreasing* function of Δ while, according to the Epps effect, the second $D_{1,2}(\Delta)$ is an *increasing* function of Δ. The paradox is that, while $R_{2,\Delta}(t)$ may “only insignificantly” differ from $R_{1,\Delta}(t)$, replacing one $R_{1,\Delta}(t)$ in the definition of $D(\Delta)$ by $R_{2,\Delta}(t)$, i.e., changing $R^2_{1,\Delta}(t)$ into

$R_{1,\Delta}(t)R_{2,\Delta}(t)$, change an increasing function into a decreasing function of Δ.

In order to elucidate this paradoxical bifurcation of the function $D(\Delta)$ under the change of $R_{1,\Delta}^2(t)$ into $R_{1,\Delta}(t)R_{2,\Delta}(t)$, let us consider, analogously to (4), the instantaneous returns

$$R_1(t) = \sum_k r_{1,k}\ \delta(t - t_{1,k})\ . \tag{56}$$

This defines a singular stochastic process with infinite mean:

$$\mathrm{E}\left[R_1^2(t)\right] = \infty. \tag{57}$$

Consider now another instantaneous returns process

$$R_2(t) = \sum_k r_{2,k}\ \delta(t - t_{2,k})\ , \tag{58}$$

and let us assume that it is only infinitesimally different from $R_1(t)$, by assuming that both tick-by-tick returns are identical ($r_{2,k} \equiv r_{1,k}, \forall\ k$), while the instants $\{t_{2,k}\}$ of the second return process are only infinitesimally different from the instants $\{t_{1,k}\}$ of the first return process:

$$t_{2,k} = t_{1,k} + \zeta, \qquad \forall\ k\ . \tag{59}$$

The time shift $\zeta \neq 0$ is supposed to be infinitesimal so that we can write

$$R_2(t) = \sum_k r_k\ \delta(t - t_k - \zeta) = R_1(t - \zeta)\ , \tag{60}$$

together with

$$R_1(t) = \sum_k r_k\ \delta(t - t_k), \qquad t_k := t_{1,k}, \qquad r_k := r_{1,k} = r_{2,k}\ . \tag{61}$$

In this case, contrary to equality (57), and notwithstanding the "infinitesimal difference" between $R_1(t)$ and $R_2(t)$, the following equality holds

$$\mathrm{E}\left[R_1(t)R_2(t)\right] \equiv 0\ . \tag{62}$$

This suggests that the resolution of the paradox rests on the fact that the so-called infinitesimal difference or shift of the tick-by-tick instants drastically changes the correlation between the different instantaneous returns, "reducing infinity to zero".

The same conclusion holds qualitatively for Δ-scale returns defined over a finite time interval Δ. Indeed, let us go from the instantaneous singular returns (61), (60) to the regular returns

$$R_{1,\Delta}(t) = \sum_k r_k \, \Pi_\Delta(t - t_k), \qquad R_{2,\Delta}(t) = \sum_k r_k \, \Pi_\Delta(t - t_k - \zeta), \tag{63}$$

where ζ is a nonzero shift. Figure 13 shows a realizations of these two Δ-scale return processes for $\zeta \gtrsim \Delta$, where both ζ and Δ are significantly smaller than mean inter-trade time duration $\bar{\tau}$. Although the Δ-scale returns $R_{1,\Delta}(t)$ and $R_{2,\Delta}(t)$ are almost identical, their product is equal to zero

$$R_{1,\Delta}(t) \cdot R_{2,\Delta}(t) = 0 \ , \tag{64}$$

which is in accordance with the Epps effect, suggesting that the function $D_{1,2}(\Delta)$ (51) is vanishing at $\Delta \to 0$.

Figure 14 shows another realization of the two Δ-scale return processes (63) now for $\zeta \lesssim \Delta$, which implies that

$$R_{1,\Delta}(t) \cdot R_{2,\Delta}(t) \equiv R^2_{2,\Delta-\zeta}(t) \neq 0 \ . \tag{65}$$

Accordingly, as can be seen in figure 14, the function $D_{1,2}(\Delta)$ (51) is equal to

$$\begin{gathered} D_{1,2}(\Delta) \simeq \frac{1}{\Delta} \mathrm{E}\left[R^2_{\Delta-\zeta}(t)\right] \simeq \nu\varepsilon_2 \, \frac{\Delta - \zeta}{\Delta}, \\ \Delta > \zeta, \qquad \Delta \ll \bar{\tau}, \end{gathered} \tag{66}$$

and increases (for $\Delta > \zeta$) with Δ increasing, in accordance with Epps effect.

Assertion 3 *In sum, the Epps effect is stipulated by the (random) shifts between respective trades instants $t_{1,k}$ and $t_{2,k}$ of different assets. Due to these shifts, the smaller the scale Δ of returns $R_{1,\Delta}(t)$ and $R_{2,\Delta}(t)$, the less likely it is that trade instants $t_{1,k}$ and $t_{2,k}$ belong to the same time interval $(t - \Delta, t)$. As a result, the Δ-scale returns $R_{1,\Delta}(t)$ and $R_{2,\Delta}(t)$ become less correlated, thus giving rise to the Epps effect. The quantitative description of the Epps effect in the framework of our model of returns is considered below.*

5.3 Epps effect: description in the frame of microstructure returns model

To quantify the Epps effect in our microstructure returns model, we calculate the two functions $D_{1,2}(\Delta)$ (51) and $\mathcal{S}^{1,2}_\Delta$ (53). For this, we need to estimate the cross correlations of the instantaneous returns

$$K_{1,2}(\tau) := \mathrm{E}\left[R_1(t) R_2(t + \tau)\right] \ . \tag{67}$$

We consider the simplest model representing the inter-dependence between $R_1(t)$ and $R_2(t)$, which reads

$$R_1(t) := R(t), \qquad R_2(t) := R(t+\zeta) \ , \tag{68}$$

where $R(t)$ is some instantaneous return process and ζ is some random delay time distributed according to some known probability density function $\kappa(\tau)$. If ζ is always positive, $R_2(t)$ can be said to be *subordinated* to $R_1(t)$ but we do not specifically need this to hold true. We do impose however that the inter-dependence between the two return processes is symmetric, which is reflected into the evenness of the probability density function: $\kappa(-\tau)=\kappa(\tau)$.

Using relations (68) and equality (23) for the correlation function $K(\tau)$, we obtain

$$K_{1,2}(\tau) := K(\tau)\otimes\kappa(\tau) = \varepsilon_2\left[\kappa(\tau)+B(\tau)\otimes\kappa(\tau)\right] \ . \tag{69}$$

We can then represent the function $D_{1,2}(\Delta)$ (51) in a form analogous to relation (43):

$$D_{1,2}(\Delta) = \frac{2\varepsilon_2}{\Delta}\int_0^\infty \left[\kappa(\tau)+B(\tau)\otimes\kappa(\tau)\right]\mathcal{T}_\Delta(\tau)d\tau \ . \tag{70}$$

To make the analytical calculations explicit, we assume for definiteness that the probability density function of the random delay time ζ is Gaussian with zero mean and variance λ^2. In our numerical calculations, we use relation (B.18) which is equivalent to expression (70).

Figure 15 shows the dependence of the function $\mathcal{S}_\Delta^{1,2}$ defined in (53) as a function of Δ, clearly demonstrating the existence of the Epps effect in the frame of our microstructure returns model. We do not present plots for different α and q values because our calculations show that the dependence of $\mathcal{S}_\Delta^{1,2}$ as a function of Δ is practically undistinguishable for different α values and for any $q>0$.

A Statistics of tick-by-tick returns

In this appendix, we give a detailed description of our tick-by-tick microstructure return model and derive its basic statistical properties.

A.1 Statistical properties of ARFIMA process

We explore the statistical properties of the tick-by-tick returns $\{r_k\}$ (7), beginning with a discussion of the correlation properties of the ARFIMA process $\{X_k\}$.

It is known that the solution of equation (8) is

$$X_k = \Upsilon \sum_{j=0}^{\infty} a_j u_{k-j}, \qquad a_j = \frac{\Gamma(j+d)}{\Gamma(j+1)\Gamma(d)}. \tag{A.1}$$

Its correlation function is equal to

$$\rho_m := \mathrm{E}\left[X_k X_{k+m}\right] = \sum_{j=0}^{\infty} a_j a_{j+m}, \tag{A.2}$$

where the $\{a_j\}$'s are defined in (A.1). Calculating the sum in (A.2) and choosing the factor Υ in (A.1) such that $\rho_0 = 1$, we obtain

$$\rho_m = \frac{\Gamma(1-d)}{\Gamma(d)} \cdot \frac{\Gamma(d+m)}{\Gamma(1-d+m)}. \tag{A.3}$$

Using the well-known asymptotical relation

$$\frac{\Gamma(d+m)}{\Gamma(1-d+m)} \simeq m^{-\alpha}, \qquad \alpha = 1-2d\ , \qquad m \gg 1, \tag{A.4}$$

we conclude that ρ_m is asymptotically a power law.

For fractional orders $d \in (0, 1/2)$ of the difference lag equation (8), the expansion (A.4) holds accurately even for small m values ($m \gtrsim 1$). With good approximation, one may thus express ρ_m (A.3) by

$$\varrho_m := \begin{cases} 1, & m = 0 \\ \digamma(\alpha)\ m^{-\alpha}, & m \geqslant 1, \end{cases} \qquad \digamma(\alpha) := \frac{\Gamma(\frac{1+\alpha}{2})}{\Gamma(\frac{1-\alpha}{2})}, \qquad \alpha = 1-2d. \tag{A.5}$$

Figure A1 illustrates the accuracy of the power law approximation (A.5) transposed in the main text as expression (12). One can observe a relative error of no more than 1.4% even for $m = 1$.

Moreover, it follows from expressions (A.3) that, for any $m \geqslant 1$,

$$\rho_m \leqslant \rho_1(d) := \frac{\pi d}{\sin(\pi d)\, \Gamma^2(d)} \ . \tag{A.6}$$

Figure A2 shows the dependence of $\rho_1(d)$ as a function of d. For any $m \geqslant 1$ and $d \in (0, 1/2)$, the correlation function ρ_m satisfies the inequality

$$0 \leqslant \rho_m \leqslant 1/2, \qquad m \geqslant 1, \qquad d \in (0, 1/2). \tag{A.7}$$

A.2 Correlation of the bid-ask bounce factor M_k

The correlation of the tick-by-tick returns $\{r_k\}$ is significantly influenced by the correlation $C_m := \mathrm{E}\,[M_k\ M_{k+m}]$ of the bid-ask bounce factor M_k defined by expression (10). Using the fact that

$$(-1)^{\xi_k + \xi_{k+m}} \equiv (-1)^{\delta_\xi(k,m)}, \qquad \delta_\xi(k,m) := \xi_{k+m} - \xi_k = \sum_{s=k}^{k+m} \iota_s \ , \tag{A.8}$$

we obtain

$$C_m = \mathrm{E}\left[(-1)^{\delta_\xi(k,m)}\right] \ . \tag{A.9}$$

Assuming that the sequence $\{\iota_s\}$ consists of iid random Bernoulli integers, equal to one with probability p and zero with probability $q = 1 - p$, this implies that $\delta_\xi(k,m)$ is, for a given m, a Binomial variable such that

$$\Pr\{\delta_\xi(k,m) = s\} = \binom{m}{s} p^s q^{m-s}, \qquad s = 0, 1, \ldots, m. \tag{A.10}$$

Accordingly, the correlation C_m is equal to

$$C_m = (2q - 1)^m \ , \tag{A.11}$$

which may be rewritten in the form (13).

A.3 Statistics of the denominator H_k in expression (7)

The iid positive random variables$\{H_k\}$ have been introduced in the definition of our microstructure return process in order to adjust the statistical properties of the tick-by-tick returns (7) to those of the empirical tick-by-tick returns.

In order to determine what should be their distribution $\varphi(\eta)$, we rewrite equality (7) in the more convenient for our subsequent analysis:

$$r_k = Y_k / H_k, \qquad Y_k = X_k M_k. \tag{A.12}$$

From the structure of M_k's, we conclude that the probability density function of each numerator Y_k is, like X_k, possess by Gaussian probability density function $\psi(y)$ with zero mean and unit variance.

We specify the probability density function $\varphi(\eta)$ of the H_k's so that the distribution of tick-by-tick returns is a fat-tail distribution similar to the empirical returns (see, for instance, [7, 8]) of the form

$$\phi(r) \sim |r|^{-\mu-1}, \qquad r \to \pm\infty. \tag{A.13}$$

Thus, we need in probability density function $\phi(r)$ of tick-by-tick returns $\{r_k\}$ (A.12), possessing by the same power tail. We suggest below that $\mu > \theta$ in order for the moments

$$\varepsilon_\theta := \mathrm{E}\left[H_k^{-\theta}\right] < \infty \tag{A.14}$$

of given order $\theta > 0$ to remain finite.

One can prove rigorously that a sufficient condition for the probability density function

$$\phi(r) = \int_0^\infty \varphi(\eta)\psi(r\eta)\eta d\eta \tag{A.15}$$

of the tick-by-tick returns $\{r_k\}$ (A.12) to possess a power law (A.13) is

$$\varphi(\eta) = \eta^{\mu-1}\Phi(\eta), \qquad \eta > 0, \tag{A.16}$$

where $\Phi(\eta)$ is nonnegative continuous function, positive at $\eta = 0$ ($\Phi(0) > 0$), and decaying, at $\eta \to \infty$, faster than $\eta^{-\mu}$. A convenient candidate for $\varphi(\eta)$ is

$$\varphi(\eta) = \frac{2b^\mu}{2^{\mu/2}\Gamma(\mu/2)}\, \eta^{\mu-1} \exp\left(-\frac{b^2\eta^2}{2}\right). \tag{A.17}$$

In this case, the probability density function $\phi(r)$ of the tick-by-tick returns is equal to the Student distribution (14). Correspondingly, the moments ε_θ (A.14) are given by the expression

$$\varepsilon_\theta = \frac{b^\theta\, \Gamma\left(\frac{\mu-\theta}{2}\right)}{2^{\theta/2}\sqrt{\pi}\, \Gamma\left(\frac{\mu}{2}\right)}. \tag{A.18}$$

A.4 Calculation of the correlation of absolute values of returns

In order to calculate the autocorrelation function (17) of the absolute values of returns, notice that $|r_k|^\theta = |X_k|^\theta / H_k^\theta$, as it follows from (A.12).

Accordingly, one has

$$\begin{gathered}
\mathrm{E}\left[|r_k|^\theta\,|r_{k+m}|^\theta\right] = \begin{cases} \varepsilon_{2\theta}\ \mathcal{F}(\theta,1), & m=0, \\ \varepsilon_\theta^2\ \mathcal{F}(\theta,\rho_m), & m \geqslant 0, \end{cases} \\
\mathrm{E}^2\left[|r_k|^\theta\right] = \varepsilon_\theta^2 \mathcal{F}(\theta,0),
\end{gathered} \tag{A.19}$$

where ε_θ is given by (A.18), while

$$\begin{gathered}
\mathcal{F}(\theta,\rho_m) := \mathrm{E}\left[|X_k|^\theta |X_{k+m}|^\theta\right], \\
\mathcal{F}(\theta,1) = \frac{2^\theta}{\sqrt{\pi}}\Gamma\left(\frac{1}{2}+\theta\right), \qquad \mathcal{F}(\theta,0) = \frac{2^\theta}{\pi}\Gamma^2\left(\frac{1+\theta}{2}\right).
\end{gathered} \tag{A.20}$$

After substitution (A.19) into (17), we obtain

$$\mathcal{A}_m(\theta) = \begin{cases} 1, & \rho = 1, \\ \dfrac{\varepsilon_\theta^2\,\widetilde{\mathcal{F}}(\theta,\rho_m)}{\varepsilon_{2\theta}\mathcal{F}(\theta,1) - \varepsilon_\theta^2\mathcal{F}(\theta,0)}, & \rho < 1, \end{cases} \tag{A.21}$$

where

$$\widetilde{\mathcal{F}}(\theta,\rho) := \mathcal{F}(\theta,\rho) - \mathcal{F}(\theta,0). \tag{A.22}$$

To calculate the function $\mathcal{F}(\theta,\rho)$, we take into account that the joint probability density function of the Gaussian variables X_k and X_{k+m} is equal to

$$\psi(x_1,x_2;\rho_m) = \frac{1}{2\pi\sqrt{1-\rho_m^2}} \exp\left(-\frac{x_1^2+x_2^2-2\rho_m x_1 x_2}{2(1-\rho_m^2)}\right), \tag{A.23}$$

and we obtain

$$\begin{gathered}
\mathcal{F}(\theta,\rho) = \frac{\Gamma(1+\theta)}{\pi}\left(1-\rho^2\right)^{\frac{1}{2}+\theta} \times \\
\int_0^{\pi/2}\left(\frac{1}{(1+\rho\sin u)^{1+\theta}} + \frac{1}{(1-\rho\sin u)^{1+\theta}}\right)\sin^\theta u\,du.
\end{gathered} \tag{A.24}$$

In particular, for $\theta = 1$, one has

$$\mathcal{F}(1,\rho) = \frac{2}{\pi}\left[\sqrt{1-\rho^2} + \rho\arcsin\rho\right]. \tag{A.25}$$

The correlation ρ_m in its attainable range (A.7) is well approximated by the first nonzero term of the Taylor expansion with respect to ρ of the function $\widetilde{\mathcal{F}}(\theta,\rho)$ (A.22), (A.24), which is given by

$$\mathcal{G}(\theta,\rho) = g_\theta\,\rho^2, \qquad g_\theta := \frac{\Gamma\left(\frac{1+\theta}{2}\right)\Gamma(\theta)}{\sqrt{\pi}\,\Gamma\left(\frac{\theta}{2}\right)}\theta^2. \tag{A.26}$$

The accuracy of the above quadratic approximation is illustrated in figures A3 and A4. In particular, figure A3 shows that the quadratic approximation $\mathcal{G}(\theta,\rho)$ (A.26) and the function $\widetilde{\mathcal{F}}(\theta,\rho)$ (A.22) are almost indistinguishable. Figure A4 plots the ratio of these two functions in order to provide a quantitive estimate of the relative errors. In the worst case for $\theta = 0.5$ and $\rho = 0.5$, we observe a maximum 5% relative error.

Replacing in (A.21) the function $\tilde{\mathcal{F}}(\theta,\rho_m)$ by its quadratic approximation (A.26), we obtain

$$\mathcal{A}(\theta,\rho) = \begin{cases} 1, & m = 0, \\ \dfrac{g_\theta\,\varepsilon_\theta^2}{\varepsilon_{2\theta}\,\mathcal{F}(\theta,1) - \varepsilon_\theta^2\,\mathcal{F}(\theta,0)}\,\rho^2, & m \geqslant 1\ . \end{cases} \tag{A.27}$$

Substituting in (A.27) the power law approximation (12) of the autocorrelation function ρ_m in place of the variable ρ, we obtain the power law (18), where the factor χ is given by

$$\chi := \Gamma^2\left(\frac{\sigma}{2}\right)\frac{g_\theta\,\varepsilon_\theta^2}{\varepsilon_{2\theta}\,\mathcal{F}(\theta,1) - \varepsilon_\theta^2\,\mathcal{F}(\theta,0)}. \tag{A.28}$$

B Statistical description of instantaneous returns

B.1 Correlation function of instantaneous returns

We outline in this subsection one of the possible derivations of relation (21) for the continuous part $B(\tau)$ of the correlation function $K(\tau)$ (20) of the instantaneous returns $R(t)$ (4).

Notice, first of all, that

$$\nu\varepsilon_2\, B(\tau) \equiv K(\tau) \qquad \forall\tau \neq 0. \tag{B.1}$$

Using definition (4) together with the ordering rule (5) of the trade instants $\{t_k\}$, we rewrite relation (B.1) in the form

$$K(\tau) = \varepsilon_2 \sum_{m=1}^{\infty} \mathcal{B}_m \,\mathrm{E}\left[\sum_k \delta(t-t_k)\delta(t-t_{k+m}+\tau)\right], \qquad \forall\tau > 0, \tag{B.2}$$

where $\{\mathcal{B}_m\}$ are the correlations (16) of the tick-by-tick returns. We keep in mind that, within the assumptions of our microstructure return model, the sequences $\{r_k\}$ and $\{t_k\}$ are mutually statistically independent. In view of identity (B.1), we rewrite (B.2) in the form

$$\nu B(\tau) \equiv \sum_{m=1}^{\infty} \mathcal{B}_m \,\mathrm{E}\left[\sum_k \delta(t-t_k)\delta(t-t_{k+m}+\tau)\right], \qquad \forall\tau > 0. \tag{B.3}$$

Applying the linear operator

$$\hat{\mathcal{L}} := \frac{1}{T}\int_0^T \ldots dt \tag{B.4}$$

to both sides of equality (B.3) and using the commutativity between linear operations and statistical expectations, we obtain

$$\nu B(\tau) \equiv \sum_{m=1}^{\infty} \mathcal{B}_m \,\mathrm{E}\left[\frac{1}{T}\int_0^T \sum_{k=1}^{N(T)} \delta(t-t_k)\delta(t-t_{k+m}+\tau)dt\right], \qquad \forall\tau > 0, \tag{B.5}$$

where $N(T)$ is the random number of instants $\{t_k\}$ belonging to the time interval $t \in (0, T)$. After integration, one has

$$\nu B(\tau) \equiv \sum_{m=1}^{\infty} \mathcal{B}_m \,\mathrm{E}\left[\frac{1}{T}\sum_{k=1}^{N(T)} \delta(t_k-t_{k+m}+\tau)dt\right], \qquad \forall\tau > 0\ . \tag{B.6}$$

Consider the limit of the last relation for $T \to \infty$. Using the Law of Large Numbers, one may replace, at $T \to \infty$, the random number $N(T)$ by its expected value $\mathrm{E}\left[N(T)\right] = \nu T$. This yields

$$\nu B(\tau) \equiv \sum_{m=1}^{\infty} \mathcal{B}_m \lim_{T \to \infty} \frac{\nu T}{T} \mathrm{E}\left[\delta(\tau - \tau_{k,m})\right], \qquad \forall \tau > 0, \tag{B.7}$$

where we have used notation (6). Using the fact that the expectation in (B.7) gives by definition the probability density function of the random interval $\tau_{k,m}$, $f_m(\tau) := \mathrm{E}\left[\delta(\tau - \tau_{k,m})\right]$, we finally obtain

$$B(\tau) \equiv \sum_{m=1}^{\infty} B_m f_m(\tau) \qquad \forall \tau > 0 \ . \tag{B.8}$$

Taking into account the evenness of the correlation functions B_m's, we obtain relation (21).

B.2 Laplace images of some generalized gamma distributions

We present analytical expressions of the Laplace images of generalized gamma distributions.

In the case $\beta = 1/2$, one has

$$\hat{f}(s) = \hat{g}_{1/2}\left(\frac{s}{\lambda_{1/2}(\vartheta)}; \vartheta\right), \qquad \lambda_{1/2}(\vartheta) = 2\vartheta(1 + 2\vartheta), \tag{B.9}$$

and

$$\hat{g}_{1/2}(s; \vartheta) = \frac{1}{2\Gamma(2\vartheta) s^{\vartheta}} \sum_{k=0}^{1} \frac{(-1)^k}{s^{\frac{k}{2}}} \Gamma\left(\vartheta + \frac{k}{2}\right) \Phi\left(\frac{k}{2} + \vartheta, \frac{2k+1}{2}, \frac{1}{4s}\right). \tag{B.10}$$

Here $\Phi(a, b, z)$ is the Kummer function (confluent hypergeometric function).

In the case $\beta = 1/3$, one has

$$\hat{f}(s) = \hat{g}_{1/3}\left(\frac{s}{\lambda_{1/3}(\vartheta)}; \vartheta\right), \qquad \lambda_{1/3}(\vartheta) = 3\vartheta(1 + 3\vartheta)(2 + 3\vartheta), \tag{B.11}$$

and

$$\begin{gathered} \hat{g}_{1/3}(s; \vartheta) = \frac{1}{6\Gamma(3\vartheta) s^{\vartheta}} \sum_{k=0}^{2} \frac{(-1)^k}{s^{\frac{k}{3}}} 2^{\frac{(k+1)(2-k)}{2}} \Gamma\left(\vartheta + \frac{k}{3}\right) \times \\ {}_1H_2\left(\vartheta + \frac{k}{3}; \frac{(2k+1)^2 + 7}{24}, \frac{41 - (2k-5)^2}{24}; -\frac{1}{27s}\right). \end{gathered} \tag{B.12}$$

Here ${}_PH_Q(\boldsymbol{a};\boldsymbol{b};z)$ is the generalized hypergeometric series, while $\boldsymbol{a}$ and $\boldsymbol{b}$ are, correspondingly, vectors of lengths P and Q.

An analogous analytical expression for the Laplace image $\hat{f}(s)$ of the probability density function $f(\tau)$ taking the form of the generalized gamma distribution with $\beta = 2/3$ is given by

$$\hat{f}(s) = \hat{g}_{2/3}\left(\frac{s}{\lambda_{2/3}(\vartheta)};\vartheta\right), \qquad \lambda_{2/3}(\vartheta) = \frac{\Gamma(3(\vartheta+1)/2)}{\Gamma(3\vartheta/2)}, \tag{B.13}$$

and

$$\begin{gathered}\hat{g}_{2/3}(s;\vartheta) = \frac{1}{3\Gamma(3\vartheta/2)s^{\vartheta}}\sum_{k=0}^{2}\frac{(-1)^k}{s^{\frac{2k}{3}}}2^{\frac{(k+1)(2-k)}{2}}\Gamma\left(\vartheta+\frac{2k}{3}\right)\times \\ {}_2H_2\left(\frac{\vartheta}{2}+a_1(k),\frac{\vartheta}{2}+a_2(k);\frac{(2k+1)^2+7}{24},\frac{41-(2k-5)^2}{24};-\frac{4}{27s^2}\right), \\ a_1(k) := \frac{(6k-5)^2+47}{144}, \qquad a_2(k) := \frac{k(13-3k)}{12}.\end{gathered} \tag{B.14}$$

B.3 Spectral representations of the expectations of quadratic returns

In the numerical calculations of the correlation functions of returns, we use relations that express the correlation functions through the corresponding power spectra. For instance, we calculate the continuous part $B(\tau)$ of the correlation function $K(\tau)$ of the instantaneous returns $R(t)$ by using the inverse Fourier transform

$$B(\tau) = \frac{1}{\pi}\int_0^{\infty}\tilde{B}(\omega)\cos(\omega\tau)d\omega. \tag{B.15}$$

Analogously, using the fact that the spectrum $\tilde{K}_\Delta(\omega)$ of the correlation function $K_\Delta(\tau)$ (38) is given by

$$\begin{gathered}\tilde{K}_\Delta(\omega) = \varepsilon_2\,\tilde{A}(\omega)\,\tilde{T}_\Delta(\omega) = \frac{\varepsilon_2}{2\pi}\tilde{\mathcal{T}}_\Delta(\omega)\left[1+\tilde{B}(\omega)\right], \\ \tilde{\mathcal{T}}_\Delta(\omega) := 2\int_0^{\infty}\mathcal{T}_\Delta(\tau)\cos(\omega\tau)d\tau = \frac{4}{\omega^2}\sin^2\left(\frac{\omega\Delta}{2}\right),\end{gathered} \tag{B.16}$$

we obtain the following relation

$$K_\Delta(\tau) = \frac{\varepsilon_2}{\pi}\int_0^{\infty}\tilde{\mathcal{T}}_\Delta(\omega)\left[1+\tilde{B}(\omega)\right]\cos(\omega\tau)d\omega\ , \tag{B.17}$$

which is convenient for numerical calculations. Similarly, we have used in our numerical calculations the relation

$$D_{1,2}(\Delta) = \frac{1}{\pi\Delta} \int_0^\infty \left[1 + \tilde{B}(\omega)\right] \tilde{\kappa}(\omega) \tilde{\mathcal{T}}_\Delta(\omega) d\omega, \tag{B.18}$$

which is equivalent to relation (70), where $\tilde{\mathcal{T}}_\Delta(\omega)$ is defined in (B.16), while

$$\tilde{\kappa}(\omega) = 2 \int_0^\infty \kappa(\tau) \cos(\omega\tau) d\tau = \exp\left(-\frac{\omega^2\lambda^2}{2}\right) . \tag{B.19}$$

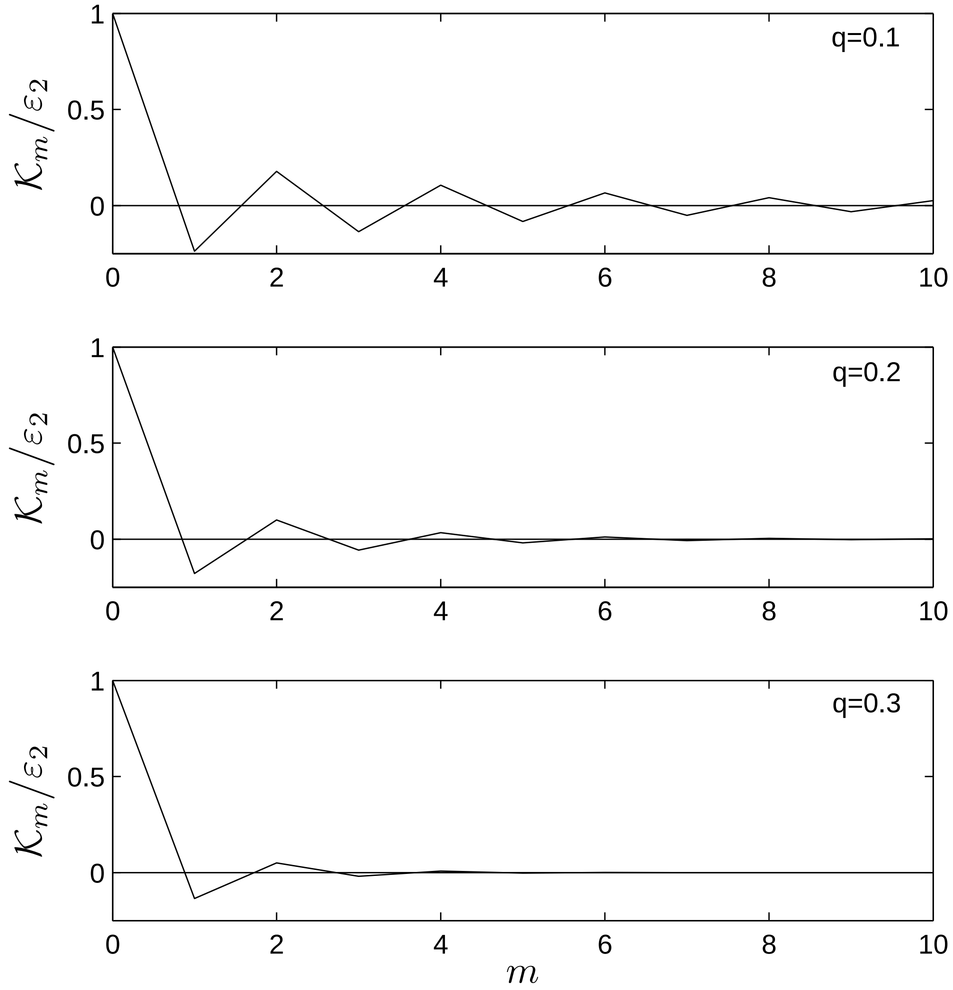

Fig. 1: Plots of the tick-by-tick returns correlation function $\mathcal{K}_m$, for $\alpha = 0.1$, $\mu = 4$ and $q = 0.1; 0.2; 0.3$ (top to bottom).

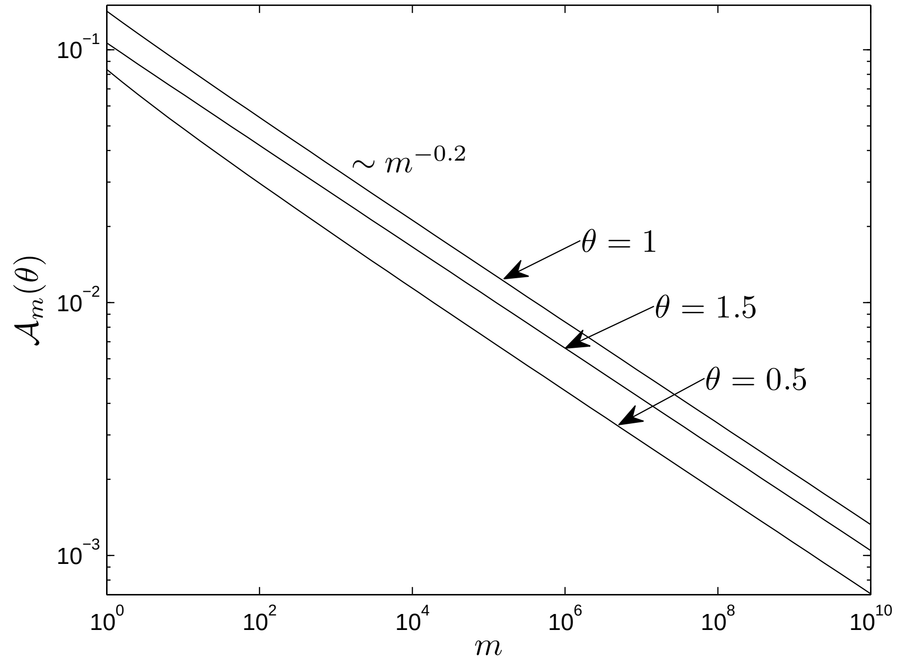

Fig. 2: Exact dependence of the autocorrelation function $\mathcal{A}_m(\theta)$ (17), for $\mu = 4$, $\sigma = 0.2$ and $\theta = 0.5; 1; 1.5$, illustrating the high accuracy of the approximate power law (18) qualified as a straight line in this log-log plot.

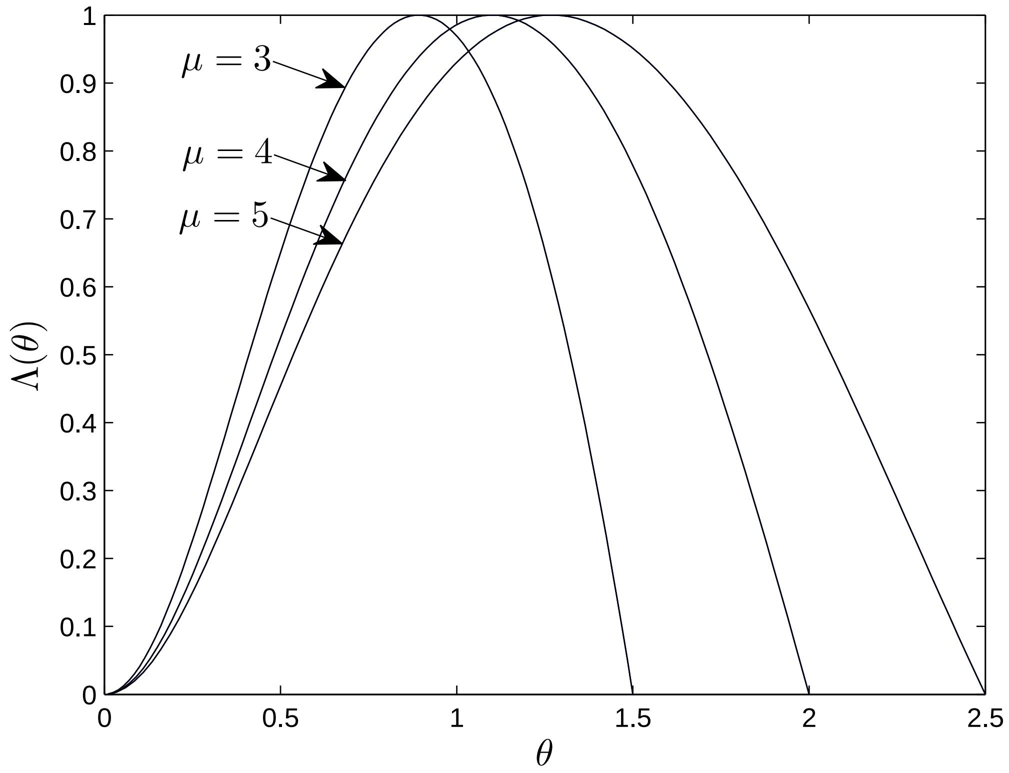

Fig. 3: Dependence as a function of θ of the normalized correlation function (19) for different values of the exponent μ of the Student distribution $\phi(r)$ (14).

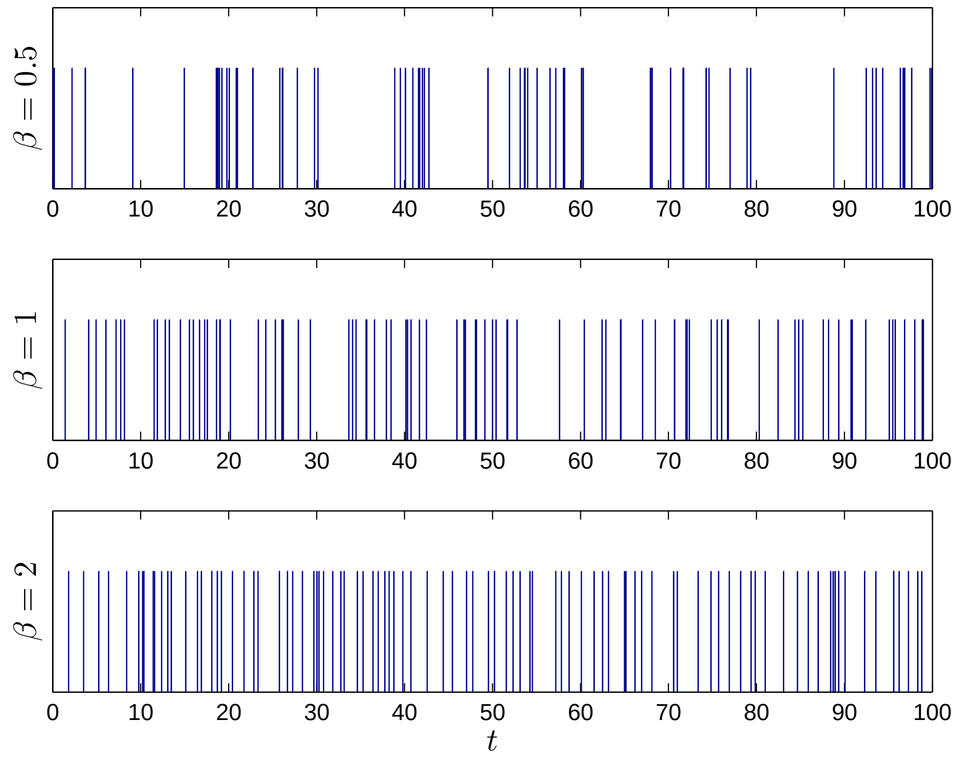

Fig. 4: Representation along the time axis of the time sequences $\{t_k\}$ of trades with $t_k = \sum_{i=1}^{k} \tau_i$, where the inter-trade intervals τ_i's are drawn from the Weibull distribution with shape parameters $\beta = 0.5; 1; 2$ (top to bottom). The corresponding values of the scaling parameter $\lambda_w(\beta)$ are given by expression (32). The value $\beta = 1$ corresponds to pure Poisson memoryless sequences $\{t_k\}$. For $\beta = 0.5$, one can observe some events clustering. In contrast, for $\beta = 2$, the time sequence is more regular, akin to quasi-periodic.

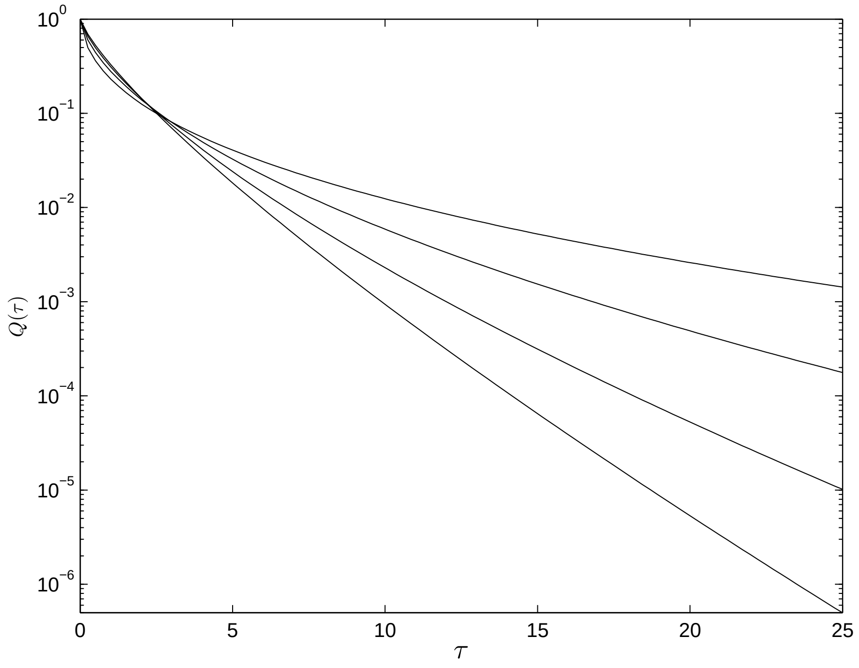

Fig. 5: Survival functions of the Weibull distribution (31) for $\beta = 0.8$ (lower curve) and of the generalized gamma distribution (34), for the same $\vartheta = 0.8$ and for $\beta = 1/3$, $1/2$ and $\beta = 2/3$ (first, second and third curves from top at the right).

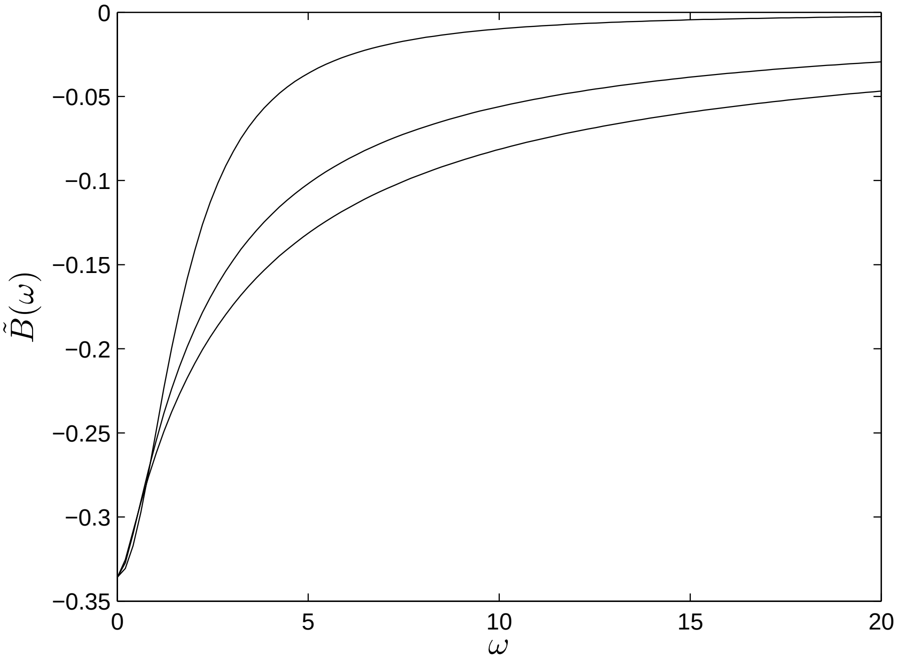

Fig. 6: Comparison of the function $\tilde{B}(\omega)$ (29) (top curve) obtained for a Poissonian statistics of the tick-by-tick times $\{t_k\}$ (36) to the two functions $\tilde{B}(\omega)$ for the GGDs for $\beta = 1/2; 2/3$ (first and second curves from bottom), for the same $\vartheta = 0.8$. The other parameters are $\alpha = 0.1$, $\mu = 4$ and $q = 0.1$.

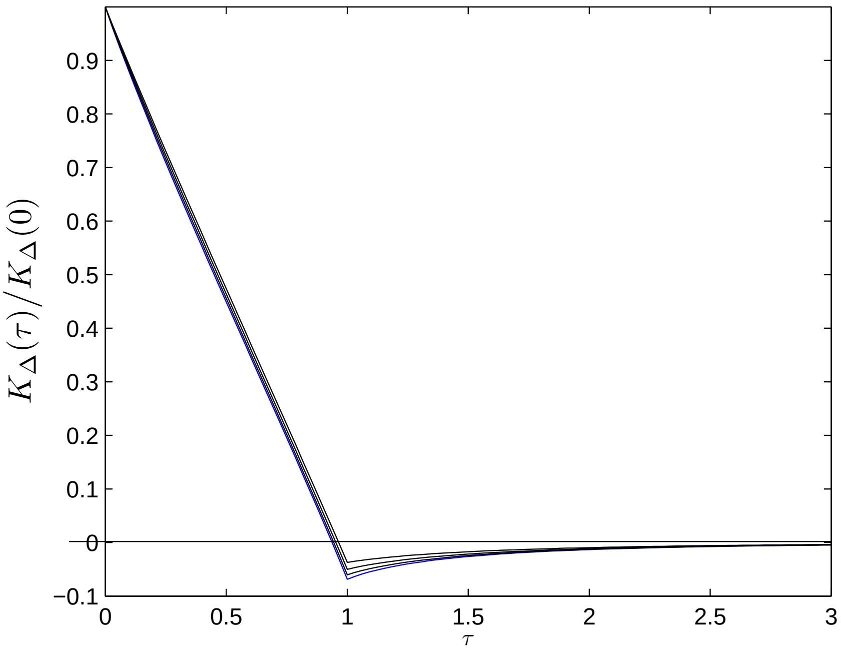

Fig. 7: Normalized correlation function $K_\Delta(\tau)/K_\Delta(0)$ of the Δ-scale returns $R_\Delta(t)$ in calendar time, for $\Delta = 1$ and $q = 0; 0.1; 0.2; 0.3$ (bottom to top). The other parameters are $\alpha = 0.1$, $\mu = 4$, $\vartheta = 0.8$ and $\beta = 2/3$. It is clearly seen that, regardless of the value of the bounce distortion probability q ($q < 0.5$), the returns $R_\Delta(t)$ in calendar time are negatively short-ranged correlated for $\tau > 1$.

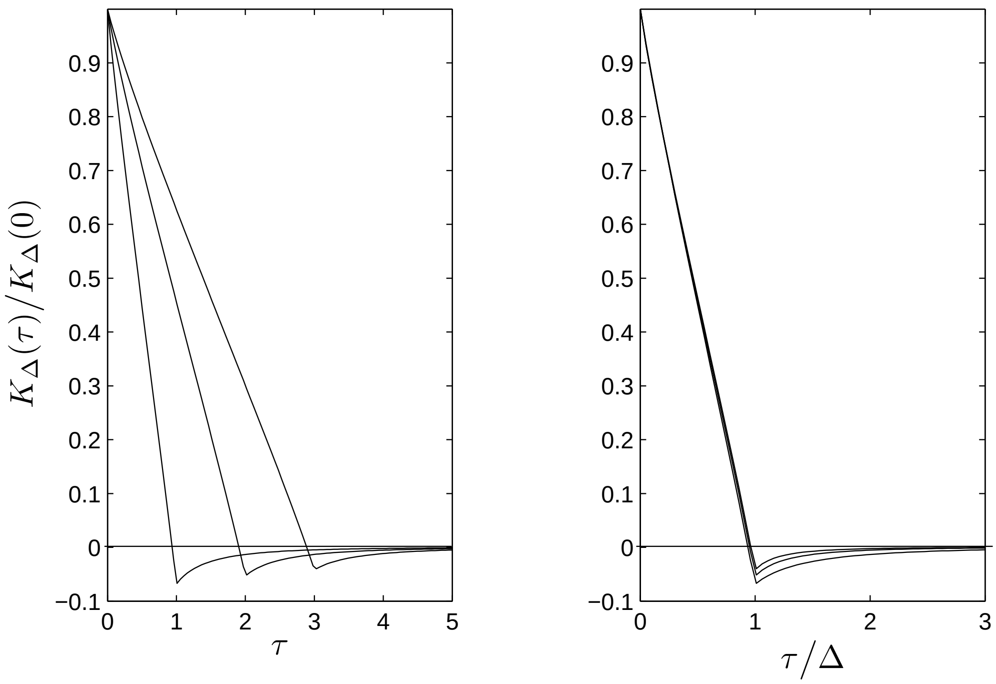

Fig. 8: Same as figure 7 for different values of Δ. Left panel: $\Delta = 1;2;3$ (left to right) and $q = 0$. Right panel: $\Delta = 1;2;3$ and $q = 0$, depicted in the calendar time scaled to Δ.

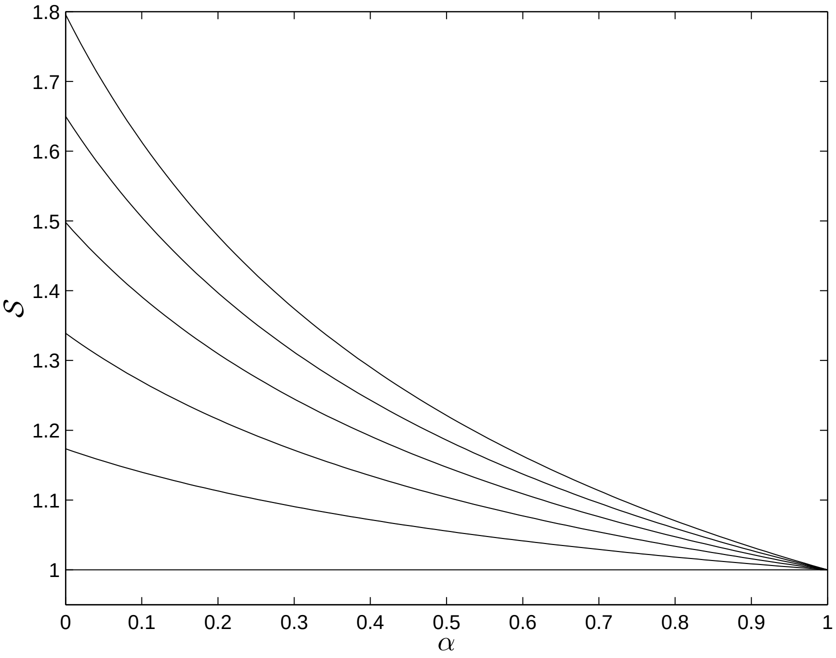

Fig. 9: Dependence of the microstructure noise strength $\mathcal{S}$ as a function of the exponent α, the exponent of the power law correlation (12) of the auxiliary ARFIMA process $\{X_k\}$. Here, $\mu = 4$. Top to bottom: $q = 0; 0.1; 0.2; 0.3; 0.4; 0.5$

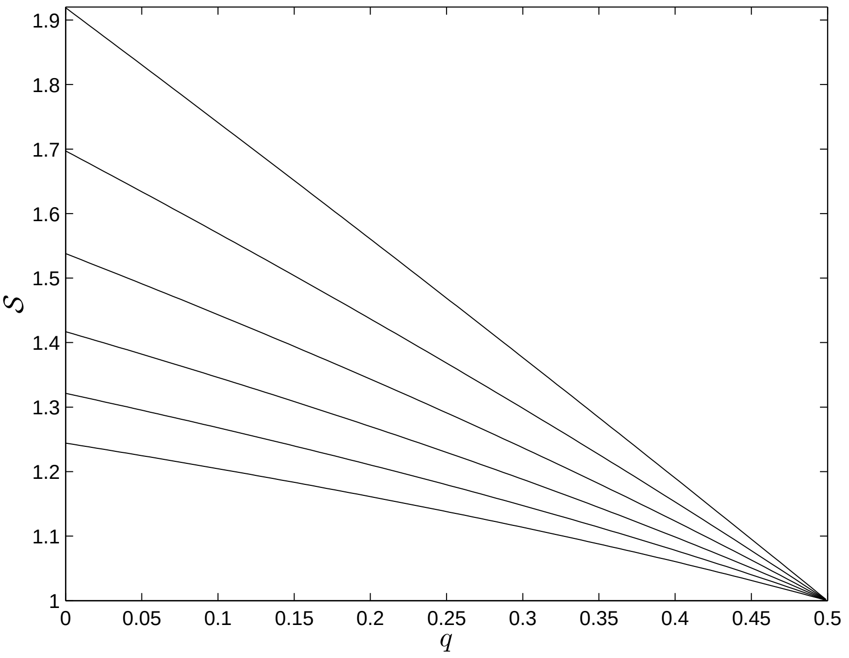

Fig. 10: Dependence of the microstructure noise strength $\mathcal{S}$ as a function of the bounce distortion probability q, for $\mu = 5$. Top to bottom: $\alpha = 0; 0.1; 0.2; 0.3; 0.4; 0.5$

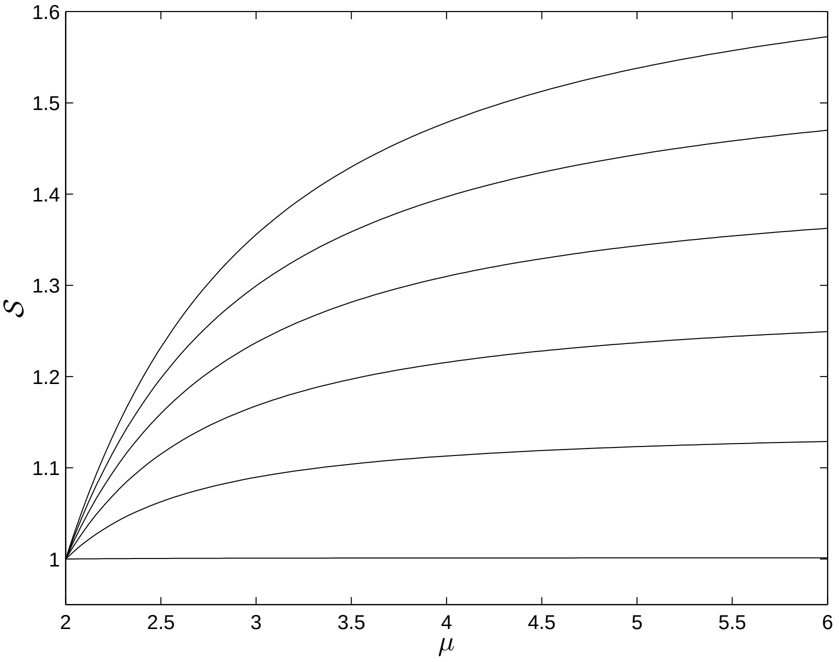

Fig. 11: Dependence of the microstructure noise strength $\mathcal{S}$ as a function of the exponent μ, the exponent of the power law describing the tail of the probability density function $\phi(r)$ (14) of the tick-by-tick returns. Here, $\alpha = 0.2$. Top to bottom: $q = 0; 0.1; 0.2; 0.3; 0.4; 0.5$

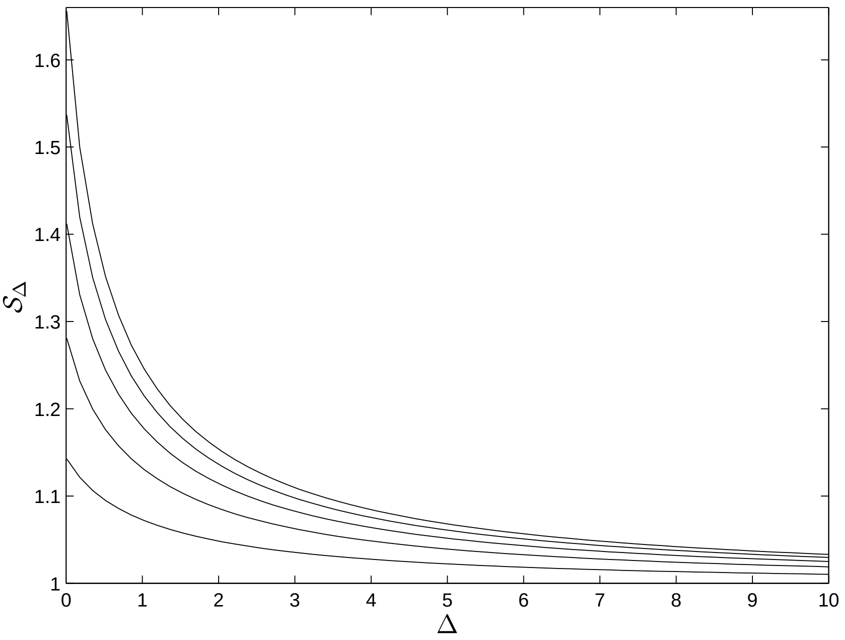

Fig. 12: Dependence of the generalized strength $\mathcal{S}_\Delta$ defined by (49) of the microstructure noise effect as a function of the interval duration Δ over which the returns $R_\Delta(t)$ are defined, for $\alpha = 0.1$ ($\sigma = 0.2$), $\mu = 5$ and for $q = 0; 0.1; 0.2; 0.3; 0.4$ (top to bottom).

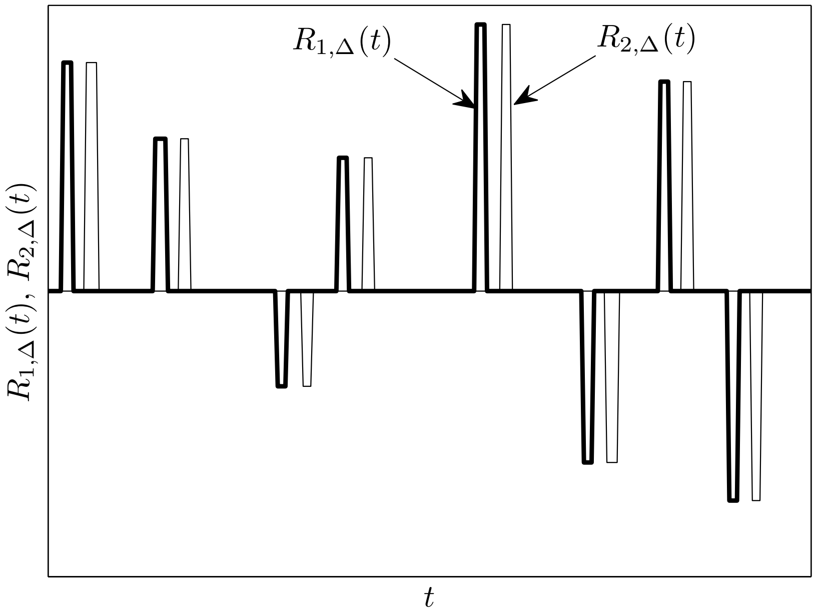

Fig. 13: A realization of the Δ-scale returns $R_{1,\Delta}(t)$ and $R_{2,\Delta}(t)$ (bold and thin lines correspondingly) for $\Delta < \zeta$, so that identity (64) is true.

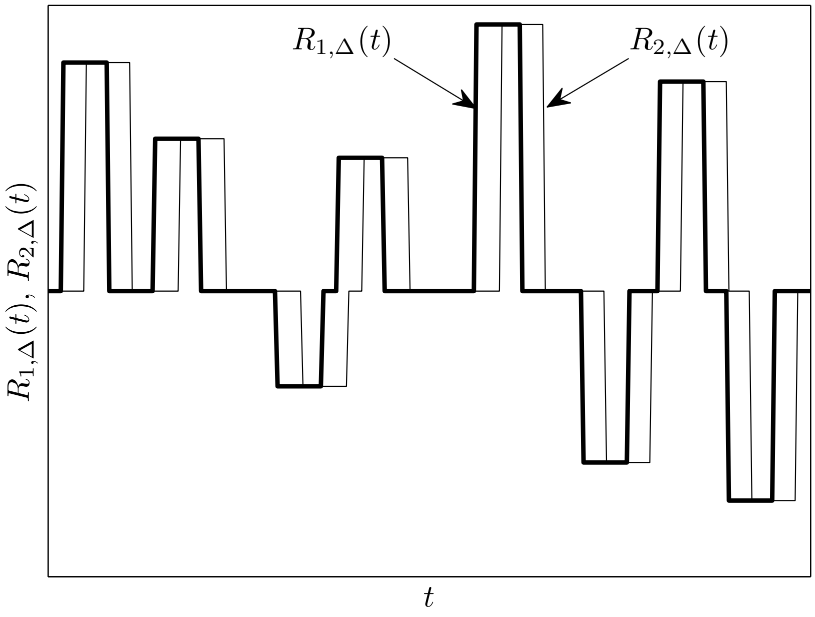

Fig. 14: A realization of the Δ-scale returns $R_{1,\Delta}(t)$ and $R_{2,\Delta}(t)$ for $\Delta > \zeta$, so that equality (66) holds.

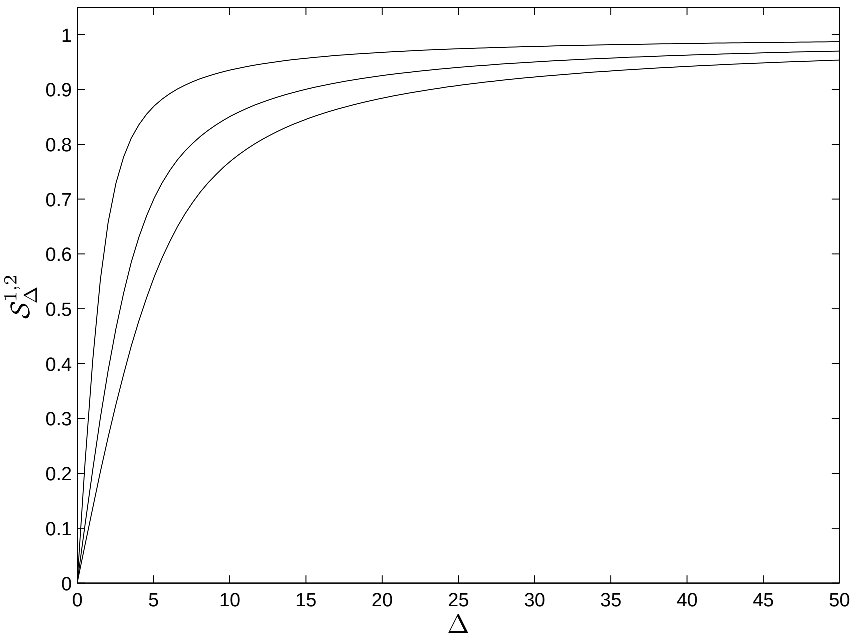

Fig. 15: Demonstration of the Epps effect in our microstructure model with the dependence of the function $\mathcal{S}_{\Delta}^{1,2}$ defined in (53) as a function of Δ, for $\alpha = 0.1$ ($\sigma = 0.2$), $\mu = 4$ and $q = 0$. Top to bottom: $\lambda = 1; 2; 3$.

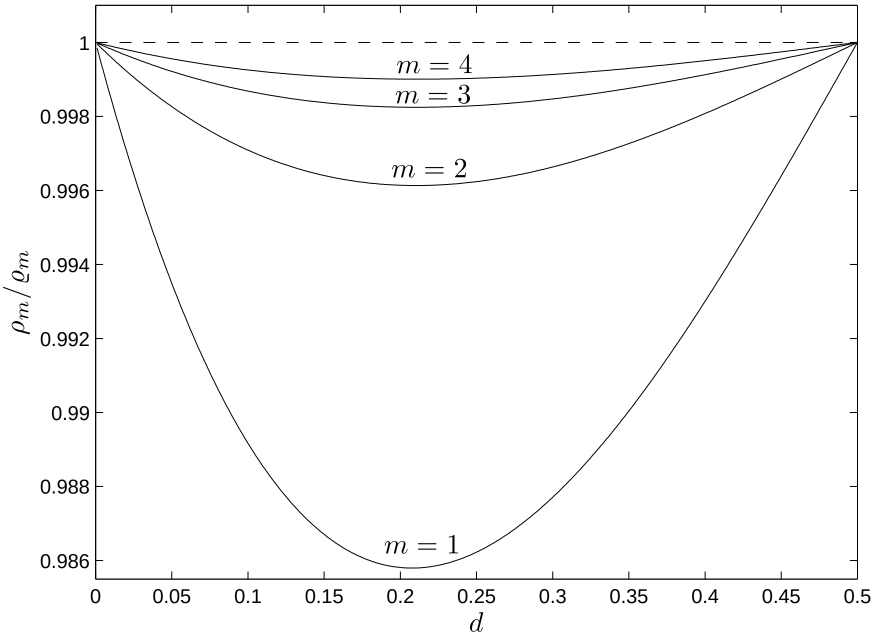

Fig. A1: d-dependence of the ratio ρ_m/ϱ_m of the correlation function ρ_m and its power law approximation ϱ_m for $d \in (0, 0.5)$, illustrating the uniform accuracy of the approximation (12).
